Department, Azerbaijan Medical University, Baku, Azerbaijan

Abstract
The aim of this work was a comparative study of the amount of antimicrobial peptides - human neutrophil peptides - defensins (HNP), hepcidin, bactericidal/permeability-increasing protein (BPI), and endotoxin in β-thalassemia. Blood samples of 135 patients with thalassemia were investigated. All patients were divided into 3 groups. The first group included patients with heterozygous form (n=45). The second group consisted of patients with homozygous form before splenectomy (n=45). The third group included patients with homozygous form after splenectomy (n=45). The age of patients varied from 2 to 18 years. Biochemical [unconjugated and conjugated bilirubin, alkaline phosphatase, hemoglobin, ferritin, aspartate transaminase (AST), alanine transaminase (ALT), mean corpuscular volume (MCV)] and immune (IgA, IgM, IgG, phagocytic activity) parameters were defined. Obtained results suggest that increased levels of endogenous antimicrobial peptides are associated with the development of the infectious process and reflect the dynamics of changes in biochemical parameters and immune status.

Materials and Methods

Objectives of the study
This work is based on the results of biochemical and immunological studies of blood samples from patients (n=135) with various forms of thalassemia at the age from 2 to 18 years (60 boys, 75 girls), of those 60 persons aged 1-4 years, 30 persons at the age of 5-7 years, from 8 to 12 years - 25 persons, from 13 to 18 years old - 20 persons. The criteria for inclusion of children in the group of survey were the confirmation of the diagnosis of β-thalassemia, clarification of its form and the patient’s age from 2 to 18 years. The diagnosis of β-thalassemia was confirmed in all children through the study of hemoglobin fractions and also on the basis of criteria for clinical picture of WHO (size of liver and spleen), child’s age at the time of the first clinical manifestations, indicator of hemoglobin at the time of diagnosis. In addition, DNA analysis was performed at Thalassemia Center in Baku to confirm the diagnosis of β-thalassemia as genotypic and define B^0, B^+, B^- as phenotypic. Splenectomy was performed in all patients at the age from 5 to 12, with the mean age of splenectomy at 8 years. All patients were divided into 3 groups: the first group included patients with heterozygous form of β-thalassemia (n = 45 persons aged 4-18 years, including 25 males and 20 females).

Introduction
According to the data from World Health Organization, there are 80-90 million of thalassemia gene carriers in the world.

This disease is found mainly in the Mediterranean countries in the Middle East, countries located in the lower part of the Pacific Ocean, and South China with the frequency of the disease gene carriers from 2% to 25%.

In Azerbaijan every year the number of patients with thalassemia increases. In some regions, this number reaches 15-20% of heterozygous carriers. Over 200 infants with homozygous β-thalassemia are born annually in republic.

Many studies have been published on biochemical changes in the immune status of patients with β-thalassemia, but the data on the study of the level of secretion of endogenous antimicrobial peptides in this disease are negligible.

Human body has complex mechanisms of defense against exogenous pathogens and internal risks (malignant growth). Defence strategy is based on the presence of a two-stage protection: non-specific (innate immune system) and specific (adaptive immune system).

Cells of immune system secrete chemokines which direct the inflammatory cells to the lesion, and the danger is eliminated by the united action of phagocytic cells, cytotoxic cells, cytokines and also antimicrobial endogenous peptides.

The aim of this work was a comparative study of the amount of antimicrobial peptides - defensin, hepcidin, protein that increases the permeability of the membranes (BPI) and endotoxin in β-thalassemia, as well as analysis of the relationship between biochemical indicators, quantity of iron and level of secretion of antimicrobial peptides.

The second group consisted of patients with homozygous form before the splenectomy (n = 45; 27 of them are girls, and 18 are boys). Patients were at age 14 months through 5 years. The third group consisted of children aged 5-12 years after splenectomy (n = 45, of which 17 are boys and 28 are girls). 20 healthy patients comprised the control group. Written informed consent from the patients was obtained, along with approval from local ethics committee.

Methods of biochemical analysis
The levels of biochemical parameters...
were determined with semi-automatic analyzer Mindray BA-88A.

Iron was determined with the photometric method using ferene, conjugated bilirubin was determined with colorimetric method with the help of diazo reagent in the acidic environment. Both indicators were measured with the help of reagents from a set of Human Diagnostics Worldwide. Activity of alkaline phosphatase in blood serum was estimated with a standardized method of end point. Activity of ALT and AST was determined with Reitman-Frankel method. Blood hemoglobin levels were measured with a photometric method using potassium ferricyanide at wavelength of 540 nm. Statistical analysis was performed using the program STATISTICA 6.0. Data are presented as mean ± standard error (SE). The Mann-Whitney U-test was used to compare the control group with the groups of patients. P<0.05 was considered statistically significant.

Hematologic and immune indicators

Determination of erythrocytic parameters [amount of erythrocytes, mean corpuscular volume (MCV) and mean corpuscular hemoglobin in erythrocytes (MCH)] was performed with the method of Cost.7

Immunoenzymatic indicators IgA, IgM, IgG were determined with Mancini method, phagocytic activity was determined on the basis of phagocytosis ability of leukocytes.8

Endogenous antimicrobial peptides

The concentration of antimicrobial peptides (defensin, endotoxin and BPI) was measured with ELISA method using commercial set of Hycult Biotech with the help of microplate reader Mindray MR-96A. The concentration of hepcidin was measured by ELISA method using commercial set of Hepcidin Prohormone Enzyme Immunoassay Kit from IBL International GmbH.

Results

Biochemical and immunological analyses of blood samples of patients in all 3 groups were carried in order to compare the dynamics of changes of antimicrobial peptides with the state of metabolism and the immune status of the studied patients. The results are shown in Table 1.

As seen from Table 1, a notable increase in the level of unconjugated and conjugated bilirubin, ALT is observed in group 3 in patients with β-thalassemia after splenectomy. Thus, conjugated bilirubin increased by 1.99 times, free bilirubin - by 1.34 times, ALT - by 2.27 times, indicating a decline in the functional state of the liver. P<0.05 compared with the control group was considered statistically significant (Mann-Whitney U-test). There is a sharp increase in the level of serum iron, ferritin in all 3 groups, thus in group 1 there is 1.9 times increase in iron; in the second group, which included patients with homozygous form of β-thalassemia before splenectomy, - 2.1 times increase, and in group 3 - 3.25 times increase, indicating the accumulation of iron in the body.

There is a notable reduction in hemo-

\(^a\)Patients with heterozygous form of \( \beta \)-thalassemia; \(^b\)patients with homozygous form before the splenectomy; \(^c\)patients with homozygous form after the splenectomy. \(^*\)P<0.001 compared with the control group (Mann-Whitney U-test).

In the neonatal period, unlike defensins, BPI is characterized by a low level of production. The content of neutrophils for newborns is 3-4 times lower than neutrophils of adults.

Data on the level of BPI also show positive dynamics of changes. As seen from Table 2, an increase of 466.2\% (4.7 times) is observed in group 1, while there are 2040.5\% (20.4 times) increase in group 2 and 3572.1\% (35.7 times) increase in group 3, indicating a significant level of changes compared with the control. P<0.001 compared with the control group was considered statistically significant (Mann-Whitney U-test).

Endotoxin is eliminated from the portal blood system of fixed macrophages, as liver is an organ needing endotoxin the most; under its stimulating effect liver produces signaling molecules needed for immunity. In case of excess supply (or accumulation) of endotoxin in the general bloodstream, endotoxin aggression is developing and, as a consequence, there firstly occurs the immune hyperactivation with allergic and autoimmune component, and then depletion of immunity with the development of immunosuppressive state. The most common cause of endotoxin aggression, and, consequently diseases, is stress. Conducted LAL test on the study of the levels of endotoxin also showed an increase in all groups of studied patients. Dynamics of changes in this indicator are similar to changes in defensin. P<0.001 compared with the control group was considered statistically significant (Mann-Whitney U-test). Thus, 5.4 times increase (545.5\%) is observed in the first heterozygous group, 7
Consequently, the number of activated neutrophils being at the stage of metabolic explosion increases dramatically in the blood of patients with thalassemia. One of the expected consequences of this process is an increased level of secretion of endogenous antimicrobial peptides by these cells and amplification of non-specific component of the immune system. It is known that transport function of iron is performed by the main iron-binding protein - transferrin, and iron is deposited as a part of ferritin, mainly in the liver. Besides, iron metabolism involves lactoferrin - iron-containing protein of neutrophils. Strengthening erythropoietic activity suppresses hepcidin synthesis, resulting in increased adsorption of iron. Tissue hypoxia directly inhibits hepcidin expression in hepatocytes, regardless of iron stores in body. Thus, hypoxia plays a leading role in the regulation of iron metabolism in patients with anemia associated with ineffective erythropoiesis.

According to Nemeth et al., suppressive effect of hemolytic anemia on the development of hepcidin is observed even in iron overload of the organism. It can be concluded that the ineffective erythropoiesis is a stronger incentive than an excess of iron, which was supposed to cause the induction of hepcidin. Such interaction of effects explains the cause of hemosiderosis in β-thalassemia. In such cases, the reduced amount of hepcidin results in iron overload of the organism, and only chelation therapy can prevent this process. In the third group, which includes patients after splenectomy, compared to the second group there is an increase of hepcidin and defensin when frequent transfusions are applied because of the possible development of the inflammatory process. Thus, the secretion of defensin and hepcidin is directly proportional to the intensity of the inflammatory process. However, erythropoiesis is crucial in hepcidin secretion in blood disease. Conclusion: the optimal mode of application of chelation therapy can be selected studying the level of hepcidin, whereas defensin is a marker of inflammatory process.

Comparison of the dynamics of changes in BPI with the level of increase in defensin shows a noticeable difference. The explanation for this is, probably, the fact that an increase in the secretion of BPI is the most common characteristic of infectious diseases of respiratory tract. Much more frequently these bacterial diseases of respiratory system such as bronchitis, pneumonia, caused by gram-negative microorganisms, are observed in patients with β-thalassemia.

Discussion

Studies conducted by a team of scientists have allowed establishing a negative correlation between the activity of natural killer cells (NK) and the amount of transfusions. Preliminary incubation of effector cells with iron chelators led to increased killer activity. These results indicate that the decrease in activity of NK cells is associated with blood transfusions and excess iron.

A comprehensive study of such morphofunctional properties of neutrophils as phagocytic activity, NBT test (nitroblue tetrazolium test) and also cytochemical figures allowed to establish the change of intracellular biochemical parameters, for example, increased activity of acid and alkaline phosphatase, peroxidase, a decrease in glycogen content, and to identify reduction in absorbent and digesting activities of these cells. The mechanism of these changes is as follows. Multiple blood transfusions, iron accumulation, frequently observed infectious complications lead to the formation of a large number of circulating immune complexes (CICs) antigen-antibody in the blood plasma of patients with thalassemia.

Phagocytosis and destruction of these complexes are implemented by phagocytes, on the other hand, phagocytes, particularly neutrophils, participate in the removal of hemolysis products from organism. Consequently, the number of activated neutrophils being at the stage of metabolic explosion increases dramatically in the blood of patients with thalassemia. One of the expected consequences of this process is an increased level of secretion of endogenous antimicrobial peptides by these cells and amplification of non-specific component of the immune system. It is known that transport function of iron is performed by the main iron-binding protein - transferrin, and iron is deposited as a part of ferritin, mainly in the liver. Besides, iron metabolism involves lactoferrin - iron-containing protein of neutrophils.

Strengthening erythropoietic activity suppresses hepcidin synthesis, resulting in increased adsorption of iron. Tissue hypoxia directly inhibits hepcidin expression in hepatocytes, regardless of iron stores in body. Thus, hypoxia plays a leading role in the regulation of iron metabolism in patients with anemia associated with ineffective erythropoiesis.

According to Nemeth et al., suppressive effect of hemolytic anemia on the development of hepcidin is observed even in iron overload of the organism. It can be concluded that the ineffective erythropoiesis is a stronger incentive than an excess of iron, which was supposed to cause the induction of hepcidin. Such interaction of effects explains the cause of hemosiderosis in β-thalassemia. In such cases, the reduced amount of hepcidin results in iron overload of the organism, and only chelation therapy can prevent this process. In the third group, which includes patients after splenectomy, compared to the second group there is an increase of hepcidin and defensin when frequent transfusions are applied because of the possible development of the inflammatory process. Thus, the secretion of defensin and hepcidin is directly proportional to the intensity of the inflammatory process. However, erythropoiesis is crucial in hepcidin secretion in blood disease. Conclusion: the optimal mode of application of chelation therapy can be selected studying the level of hepcidin, whereas defensin is a marker of inflammatory process.

Comparison of the dynamics of changes in BPI with the level of increase in defensin shows a noticeable difference. The explanation for this is, probably, the fact that an increase in the secretion of BPI is the most common characteristic of infectious diseases of respiratory tract. Much more frequently these bacterial diseases of respiratory system such as bronchitis, pneumonia, caused by gram-negative microorganisms, are observed in patients with β-thalassemia.

Conclusions

The following conclusions can be summarized:

- An increased secretion of defensin is observed in homozygous form of β-thalassemia; 5.1 times increase before splenectomy and 15.4 times increase after splenectomy, against the background of lower phagocytic activity of leukocytes and decreased functional state of liver.
- Accumulation of iron is observed in the group of patients with β-thalassemia with frequent transfusions and, an increase of the endotoxin concentration in blood plasma occurs against this background.
- The optimal mode of application of chelation therapy can be selected taking into account the level of hepcidin.
- Frequent infectious complications lead to increased secretion of BPI.
- Increase in the level of endogenous antimicrobial peptides is the marker of infection process and reflects the dynamics of changes in biochemical parameters and immune status.
